Abstract

Vegetable drying is an alternative method to curb post harvest decay of vegetables and a process to produce dried vegetables, which can be directly consumed or used as ingredients for the preparation of soups, stews, baby foods, cakes, puddings, and many other foods. In this study, the effect of ultrasound frequency and sonication time as pre-treatment prior to air drying at 70°C at an air velocity of 0.5 m/s, on carrot drying kinetics, flavour, colour, and non-enzymatic browning was investigated using a 3-level factorial response surface method. The result showed that an increase in sonication frequency and time did not significantly increase moisture diffusivity but in comparison with the control, water diffusivity increased after ultrasound application and the overall drying time was reduced. Application of the ultrasound pre-treatment in distilled water resulted in water gain and sugar loss, indicating that the ultrasonic pre-treatment can be an important step to produce low sugar content dried products. The brightness and redness to yellowness values of the ultrasonically pre-treated dried carrots were better than those without ultrasound application. In comparison with the flavour of the control, the ultrasound pre-treated samples recorded higher flavour response signals, indicating that the application of ultrasound improved the flavour of the dried carrot. The variation in sonication frequency and time did not significantly affect the non-enzymatic browning index of the dried products but were better than the control.

Introduction

Carrot (*Daucus carota* subsp. *Sativus*) is a root vegetable, which originated in the Indo-European area. Production of carrot and turnip in 2010 was estimated to be 35 million tonnes (FAO, 2010). With 15.899078 million tons, China was by far the largest producer and accounted for over 45.2% of the global output, followed by the USA (1.32437 million tons), Uzbekistan (1.107 million tonnes), Poland (0.814932 million tonnes), and the United Kingdom (0.7479 million tons). The crop is a good source of vitamin C, vitamin B6, folate, pantothenic acid, iron, potassium and copper, and a very good source of dietary fibre, vitamin A (which enhances vision), vitamin K, and manganese.

The relatively high moisture content of carrot makes it a highly perishable crop and it deteriorates quickly at postharvest. Therefore, it is necessary to apply appropriate postharvest technology to prolong its shelf life. Drying is among the most popular methods used to produce several dried vegetables which can be consumed directly or used as ingredients for preparation of soups, stews, baby foods, cakes, puddings, and many other foods (Azoubel *et al.*, 2010; Fernandes *et al.*, 2008a, 2008b; Nguyen and Price, 2007; Karim and Hawlader, 2005). Nonetheless, conventional hot air drying can cause excessive quality deteriorations to the flavour, colour composition, vitamins, and essential amino acids of the final product (Mujumdar and Menon, 1995). The simultaneous heat and mass transfer process accompanied by phase change makes conventional hot air drying an energy intensive and consequently expensive process. Hence, a pre-treatment can be applied to reduce the initial water content or to modify the vegetable tissue structures so that air drying can become faster (Fernandes and Rodrigues, 2007). Among with the most reported pre-treatment technique used prior to drying, osmotic dehydration is common (Antonio *et al.*, 2008; Pani *et al.*, 2008; Lombard *et al.*, 2008, Fernandes *et al.*, 2008b; Azoubel *et al.*, 2009). However, among the emerging new technologies, ultrasound-assisted drying is very promising because the process can be carried out at a low temperature, which reduces the probability of food degradation (Mason, 1998) and permits the removal of moisture content from solids without producing a liquid phase change (Azoubel *et al.*, 2010). Ultrasound applications in the food industry are on the increase as new uses are being studied (Fernandes *et al.*, 2008a, 2008b).

The ultrasonic pre-treatment involves the immersion of the vegetables in water or in a hypertonic aqueous solution to which ultrasound is applied. In solid materials, ultrasound waves generate alternative compressions and expansion, and consequently produce a spongy effect similar to that observed when a sponge is squeezed and released repeatedly (De la Fuente *et al.*, 2006). The spongy effect causes the ejection of liquid from the inner part to the surface of the vegetables and the entry of fluid from the outside. Muralidhara *et al.* (1985) reported that the forces involved in this mechanism can exceed the

surface tension, which maintains the water molecules inside the capillaries of the material, setting up microscopic channels that reduce the diffusion boundary layer, and thus making it easier to exchange matter. Therefore, ultrasound application in solid materials changes the viscosity and surface tension, and cause solid structural deformation (Cárcel *et al.*, 2011). Although some works report the study of ultrasound pre-treatment on drying (Fernandes and Rodrigues, 2007; Fernandes *et al.*, 2008a, 2008b; Azoubel *et al.*, 2010), there are no reports on variation of ultrasound frequencies as a pre-treatment prior to drying in the scientific literature.

The objective of this study was to investigate the variation of ultrasound frequency and time as pre-treatments and its effect on the drying kinetics, colour, flavour, and non-enzymatic browning of carrot.

Materials and methods

Materials

Fresh carrots were obtained in the local market of Zhenjiang, China, at a stage of ripeness ideal for processing. The carrots were washed with drinking water and machine sliced to 10 mm thickness. These were manually sliced into 10 mm cubes and kept in the refrigerator at 4°C until use. The initial moisture content was determined gravimetrically by heating 5 g of the samples at 105°C for 24 h. The initial total soluble solid (Brix) was determined by refractometry to be 8.67° Brix.

Experimental design

A 3-level factorial response surface methodology was used to design the experiment. The effect of two factors was used: ultrasound frequency (range 24-40 kHz) and sonication time (range 10-60 min).

Ultrasound pre-treatment

An experimental set consisting of carrot cubes was immersed in distilled water and subjected to ultrasonic waves at frequencies of 24, 32, and 40 kHz for 10, 35 and 60 min. The accuracy of the ultrasonic frequency was ± 1 kHz. These pre-treatment frequencies and times were chosen based on industrial practice. The water to fruit ratio was maintained at 4:1 on the basis of weight.

The ultrasonic pre-treatments were carried out separately in an online laboratory scale ultrasonic bath system (Jiangsu University model no. 20084798) having five sweep frequencies in the range of 22-68 kHz at maximum power of 18 W. The parameters of the ultrasound pre-treatment chosen for the experiment were 300 ms for period, 10 s for ultrasound working time, and 3 s for ultrasound rest time. The experiment was carried out under ambient temperature of 29°C in an ultrasonic bath without mechanical agitation.

After the samples were removed from the water solution, they were drained and blotted with absorbent paper to remove excess water. The weight was determined and samples were subjected to drying. The temperature was measured before and after the runs and the increase in temperature during the runs was within 2°C. Each run was duplicated for the drying experiment. At the end of the ultrasound pre-treatment, samples were taken to determine its total soluble solids by refractometry. This step was undertaken to quantify the amount of sugar that the carrots lose by mass transfer to the water medium.

The weight and moisture content of the samples, and the sugar content of the carrot cubes were used to determine the water loss (WL) and solid gain (SG), following equations 1 and 2.

$$WL (\%) = \frac{w_i M_i - w_f M_f}{w_i} \times 100 \quad (1)$$

$$SG (\%) = \frac{w_f X_f - w_i X_i}{w_i} \times 100 \quad (2)$$

where:

M_i and M_f are the initial and final moisture content on a wet basis (g water/g);

w_i and w_f are the initial and final vegetable mass (g);

X_i and X_f are the initial and final carrot soluble solid content (g solid/g).

Air-drying

After removal from the ultrasonic bath, the samples were drained, blotted with absorbent paper to remove excess water solution and transferred to a forced air dryer (Jiangsu University) set at 70°C and air velocity of 0.5 m/s. The schematic diagram of the dryer used in this experiment is shown in Figure 1. This temperature was chosen based on industrial practices and optimisation studies carried out previously (Abano and Sam-Amoah, 2011). Carrot cubes (50 g) were placed in the dryer sample holder for air-drying. During drying, the samples were weighed every 15 min in the first 2 h and later at 30-min intervals until the dynamic equilibrium between the sample moisture content and drying air humidity was reached, *i.e.* when the sample weight became constant. The data were used to compute the water diffusivity of carrot during air-drying at 70°C according to Fick's Law of diffusion. The equation used for the falling rate period of the drying process was based on the simplification of Fick's second law considering long processing period (Perry and Green, 1999). The coefficient of moisture diffusivity was adjusted using Eq. (3) with a parameter estimation procedure based on least squares:

$$\frac{\partial M}{\partial t} = -\frac{2\pi}{L^2} D_{\text{eff}} (M - M_e) \quad (3)$$

where:

D_{eff} is the effective water diffusivity (m^2/s);

M is the moisture content (g $\text{H}_2\text{O}/\text{g}$ dry matter);

M_e is the equilibrium moisture content (g $\text{H}_2\text{O}/\text{g}$ dry matter);

t is the time (s); and

L is the thickness of the sample (m).

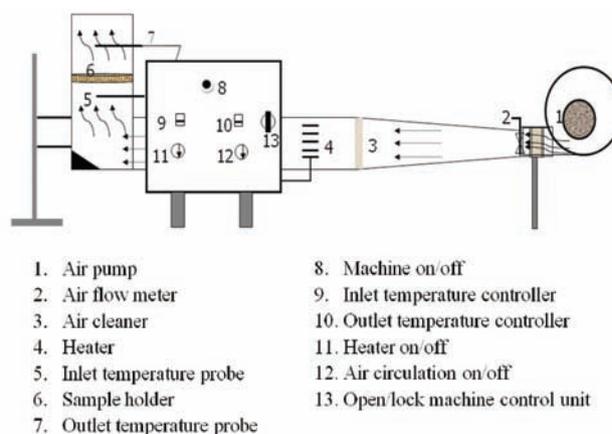

Figure 1. The hot air dryer and associated units.

The D_{eff} was obtained by fitting the experimental data to the Fick's diffusion model, using the non-linear estimation resources of SPSS 16.0 (SPSS Inc., Chicago, IL, USA). The thickness of either the fresh carrot or the ultrasonically pre-treated carrot was assumed as the initial dimension. The Page model (Page, 1949) (one of the most useful empirical models) was used to fit the experimental drying data. The Page equation is written according to the formula:

$$\frac{M - M_e}{M_0 - M_e} = MR = \exp(-kt^n) \quad (4)$$

where:

M is moisture content at time t ;

M_0 is the initial moisture content;

M_e is the equilibrium moisture content (all in g H₂O/g dry matter);

k is the drying rate constant in min⁻¹;

n is the dimensionless model parameter;

t is the process time in min.

The goodness of fit of the model was characterised by the residual sum of squares (RSS), root mean square error (RMSE), reduced chi-square (χ^2), and the determination coefficient R^2 , according to the equations below.

$$RSS = \sum_{i=1}^N (MR_{\text{expt},i} - MR_{\text{pred},i})^2 \quad (5)$$

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (MR_{\text{expt},i} - MR_{\text{pred},i})^2} \quad (6)$$

$$\chi^2 = \frac{\sum_{i=1}^N (MR_{\text{expt},i} - MR_{\text{pred},i})^2}{N - z} \quad (7)$$

where:

$MR_{\text{expt},i}$ and $MR_{\text{pred},i}$ are the experimental and simulated dimensionless moisture ratio (MR) respectively;

i is the experimental observation in a given run for a total of N number of observations; and

z is the number of model parameters (2 in the Page model).

The drying rate constants (k) and dimensionless model parameter in the Page equation (n) were determined with nonlinear regression of SPSS 16.0 (SPSS Inc.).

Colour measurements

The colour of the fresh and dried tomato slices was measured in Hunter parameters with an automatic colour difference meter (DC-P3, Beijing, China). The calibration is standardised by placing the tip of the measuring heat flux against the surface of the white and black calibration plates. After standardisation, three random readings were recorded; the colour brightness coordinates (L) measures the whiteness value of a colour and ranges from black (0) to white (100). The chromaticity coordinates i) measures the red when positive and green when negative, and the chromaticity coordinate ii) measures yellow when positive and blue when negative and both range from -60 to +60.

Flavour measurement

The electronic nose system for agricultural products consisting of nine sensitive tin dioxide semiconductor sensors was used to monitor the flavour of the fresh and dried carrot. The instrument was previously described by (Xiaobo and Jiewen, 2008). Three and a half (3.5) grams of the fresh and reconstituted dried samples were sealed in the concen-

tration chamber and incubated at a temperature of $27.0 \pm 0.09^\circ\text{C}$. Thereafter, the samples were left to sit to enable the volatilisation of the flavour compounds into the headspace and were then pumped into the sensor chamber at a constant flow rate of 150 mL/min. The sensor response pattern signal was measured using pattern recognition algorithms controlled by a commercial acquisition board computer program PCL-816 (Advantech Inc., Taiwan, China). Sensor patterns were monitored until stable values were recorded by all nine sensors. Measurements were recorded in resistance changes experienced by the sensors when exposed to the flavour compounds.

Non-enzymatic browning determination

A modified method of Cernișev (2010) was used to determine the browning index (BI) of the dried carrots. The degree of browning was evaluated as browning index measured as absorbance at 440 nm which was the wavelength for maximum elution of brown pigment in the dried products using 60% ethanol for extraction. Brown pigments were extracted from 0.8 g test portions from the dried carrot samples. Samples were ground into fine powder with a kitchen blender for 90 s after which 20 mL of ethanol (60%, v/v) was added and allowed to stand for 12 h after which the mixture was agitated and then filtered through 0.45- μm nylon filter membrane. Browning index of filtrates was evaluated with a spectrophotometer (UNICO 7200, Shanghai, China) against 60% ethanol as blank. All samples were extracted in duplicate.

Statistical analysis

Type III 3-level factorial analysis of variance (ANOVA) was carried out on the non-enzymatic browning index, colour brightness and ratio of redness to yellowness to ascertain the statistical significance of the terms in a second-order polynomial model. The Design Expert 8.0.7.1 statistical package (Stat-Ease Inc., USA, 2010) was used for the ANOVA at a probability of 5%. The accuracy of the model to describe the response variables was diagnosed against the normal probability plots of the residuals, the predicted *versus* actual plots, and the coefficients of determination (R^2) values. The 3-D surface plots for two factors were generated for the various responses. Average values for triplicates were reported for all measurements with the exception of non-enzymatic browning where it was a duplicate.

Results and discussion

Effect of ultrasonic pre-treatment on water loss and solid gain

Table 1 presents the effect of ultrasonic pre-treatment on WL and SG. The results show that during ultrasound pre-treatment, the carrot cubes gained water and lost sugar. Fernandes and Rodrigues (2007), Fernandes *et al.* (2008), Azoubel *et al.* (2010) found similar results in the ultrasonic pre-treatment of banana *cv. Navica*, melon, and banana *cv. Pacovan*, respectively. This was due to the concentration gradient that favours mass transfer of sugar from the carrot to the water medium and mass transfer of water to the carrots. Consequently, the moisture content of the fruit vegetable after ultrasonic treatment increased (3.78% at 40 kHz for 10 min)

Drying

The dimensionless moisture content was calculated and its change during drying up to the dynamic equilibrium point of the various pre-treated and the control carrots is presented Figure 2. As expected, the moisture content decreased with drying time and followed an exponential decay. The mathematical modelling of the drying data using Eq. 4 for the fresh and pre-treated carrot at 70°C air temperature is also shown in Figure 3. Table 2 shows the Page's parameters for the carrot samples. It can be seen that the k parameter was fairly constant for the control and ultrasound pre-treated samples even though it was highest in the ultrasonic pre-treated samples at 32 kHz for 10 min. The n parameter was also higher in the ultrasound pre-treated samples than the control, except for the 32 kHz for 60 min ultrasound pre-treated samples. Azoubel *et al.* (2010) dried bananas pre-treated at 24 kHz for 10, 20, and 30 min at 50 and 70°C and found k parameter in the Page model to increase with air temperature (except the samples pre-treated for 30 min). The same behaviour was found for n parameter (except for the 30 min ultrasound pre-treated samples). Azzouz *et al.* (2002) concluded that n was a function of air velocity and initial moisture content, while k was a function of air temperature and initial moisture content of grapes.

The Page empirical model clearly fits the experimental data when compared with the results obtained using the diffusion model, with RSS less than 0.003, RMSE less than 0.00913, reduced χ^2 less than

0.010, and R^2 greater than 0.998. The high values of R^2 , and low values of RSS, RMSE, and χ^2 recorded in Table 2 show that the experimental data are very similar to the simulated data for the Page model around logarithmic curves throughout the drying process. Previous authors have used this model to accurately simulate the drying of banana (Azoubel *et al.*, 2010), kiwi (Simal *et al.*, 2005), and tomatoes (Abano *et al.*, 2011), among others. The measured and simulated graph shown in Figure 4 indicates good prediction agreement between the experimental and simulated values of dimensionless moisture content data.

Fick's parameters for the control and pre-treated carrot are shown in Table 3. The effective coefficient of diffusivities of water calculated using the dimensionless moisture ratio (Eq. 3) were higher for the ultrasound pre-treated samples but the effect may not be so great with temperatures above 70°C. This is consistent with the observations of Fuente-Blanco *et al.* (2006) that the ultrasonic pre-treatment affects fruit vegetable tissue, making it easier for the water to diffuse during air-drying. Fernandes *et al.* (2008b) studied the cell structure of melon after ultrasonic pre-treatment using microscopic light and observed that this phenomenon may happen due to the process of formation of micro-channels when ultrasound is applied. Water could use the microscopic channels as an easier pathway to diffuse toward the surface of the fruit vegetable, contributing to the higher values of moisture diffusivity in ultrasound pre-treated samples.

Quantitatively, the increasing moisture diffusivity due to the appli-

cation of ultrasound has great significance during the air drying process. For instance, if carrots are dried to a final moisture of 25% wet basis (33% dry basis), which is the maximum moisture content value allowed for most dried fruits and vegetables, it will take 256 min to dry the samples without ultrasound at 70°C, while by subjecting the carrots cubes to 32 kHz ultrasound pre-treatment, in distilled water for 10, 35, and 60 min, the drying times will be reduced to 178 min (30.47%), 149 min (41.79%), and 141 min (44.92%), respectively.

This will optimise processing time, reducing drying time to a minimum, reducing costs, and ultimately increasing overall productivity, as observed by Jambrak *et al.* (2007), Fernandes and Rodrigues (2007), Fernandes *et al.* (2008a, 2008b, 2009) and Azoubel *et al.* (2010) for ultrasonic assisted drying of button mushrooms, Brussels sprouts, cauliflower, pineapples, melons, and bananas. The moisture diffusivity values recorded in this experiment lie within the general range of 10^{-12} – 10^{-8} m²s⁻¹ for drying of food materials.

Effect of ultrasound on carrot flavour

Untransformed maximum flavour response signals by nine SNO₂ sensors of fresh, control, and ultrasonic pre-treated dried carrot cubes are shown in Figure 5A. It can be clearly seen that the flavour of the dried carrot in comparison with the fresh was degraded. However, compared with the flavour of the control, the ultrasound pre-treated sam-

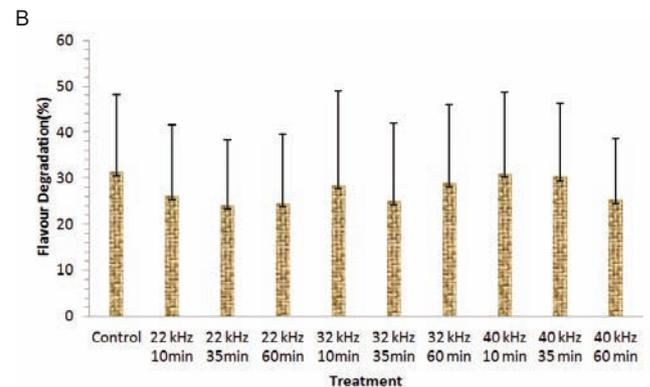

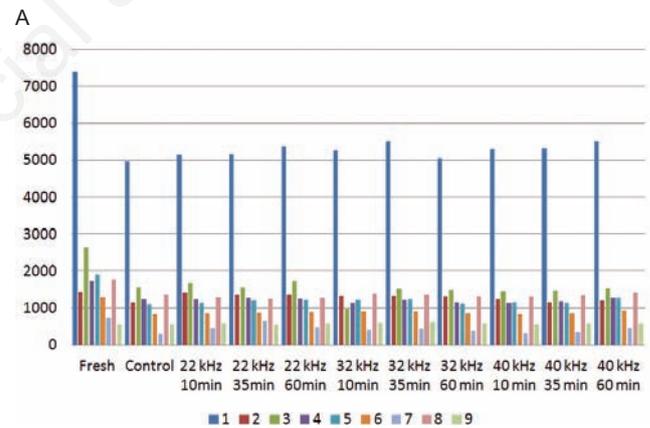

Figure 5. (A) Untransformed maximum flavour response signal by nine SNO₂ of fresh, control, and ultrasonic pre-treated carrot; (B) Mean flavour degradation (%) of nine SNO₂ sensors of the control and the ultrasonic pre-treated dried carrot in comparison with the fresh.

ples recorded higher flavour response signals. Thus, the application of ultrasound improved the flavour of the dried carrot. This is further supported by the mean flavour degradation response by the nine tin dioxide sensors (Figure 5B). The average flavour deterioration was 31.43% for the control samples while in the case of the ultrasound pre-treated samples, the degradation ranged between 24.38% and 30.39%. The flavour of food is very important for its acceptability and a slight change in the flavour of processed food may affect the overall quality of the product. Degradation in flavour after dehydration has been reported. A distinct difference in flavour has been found in dried products compared to fresh ones as a result of heating (Hui and Clark, 2007). Lin *et al.* (1998) studied the flavour properties of vacuum-microwave-dried and air-dried carrot slices, which were first blanched in water. The vacuum-microwave-dried carrot slices received higher ratings for texture, flavour and overall acceptability as compared to the air-dried carrot slices, even though the flavour was degraded for both processing methods. Flavour degradation was also reported for tomato pomace dried at air temperatures of 50-90°C (Al-Muhtaseb, 2010). However, the tomato pomace dried at 50°C and 60°C were rated superior in flavour quality attributes to those dried at 80°C and 90°C. The lower response signals by the electronic nose for the dried samples may be an indication that the associated enzymes responsible for producing the flavour of fresh

carrots were inactivated as a result of heating in the control (Goodman *et al.*, 2002) but the ultrasound pre-treatment improved the enzyme activity. The general degradation in flavour of the dried products agrees with previous reports by (Abano *et al.*, 2012; Vadivambal and Jayas, 2007; Alibas *et al.*, 2007; Contreras *et al.*, 2008) for dried products.

Effect of ultrasound on colour of dried carrot

Colour change is another criterion for assessing the quality of dried products. The closer it is to the fresh carrot, the better consumers prefer it. Arslan and Özcan (2008) reported that higher values of brightness (L^*) and ratio of redness to yellowness (a^*/b^*) are desirable in dried carrot. Consumer preference studies of fresh carrot indicated that high a^* and a^*/b^* values are preferred. On the above basis, the ultrasonic pre-treated dried carrot at 24 Hz for 10 and 60 min would be preferred over the control (L^* : 66.95, a^*/b^* : 0.556) and others (Table 4). There was a statistical difference in the linear and quadratic effect of ultrasound frequency on the L^* value of the dried samples (Table 5). The increase in ultrasound frequency improved the luminance of the dried products. Sonication time, however, did not statistically improve the brightness of the dried carrot. In addition, the increase in ultrasound frequency did not significantly decrease the a^*/b^* values. When the colour values of dried

carrots were compared with the fresh (L^* : 48.35, a^*/b^* : 0.641) there was enhancement in brightness and a general reduction in a^*/b^* . There was a significant difference in the colour of the control (L^* : 66.95, a^*/b^* : 0.556) to the ultrasound pre-treated values (Table 4). Colour deterioration has been studied by several researchers for a number of products. Harbourne *et al.* (2009) reported that the drying method had a significant effect on the colour of meadowsweet extracts. Thermal processing and a non-enzymatic browning reaction was found to cause the colour changes in marigold which led to the destruction of pigments present in the petal (Wanyo *et al.*, 2011). Prabhanjan *et al.* (1995) studied the thin-layer drying of carrot (*Daucus carota*) and showed that product dried by conventional air drying and microwave drying at half the power level retained good colour while those dried at maximum microwave power were dull. The colour of the final dried carrot may be strongly related to the beta-carotene in carrot that is known to possess enormous health benefits. The general decreasing trend of a^*/b^* suggests less browning and may be the result of less Maillard reaction. The response surface plots of L^* and a^*/b^* for the dried tomato slices as well as their respective normal probability plots and simulated *versus* experimental plots are shown in Figures 6-11.

Effect of ultrasonic pre-treatment on browning index

Non-enzymatic browning is another quality indicator in the drying of carrot. The extent of browning is mainly attributed to the colour changes resulting in Maillard reactions in the carrot (Zanoni *et al.*, 1999). The response of the non-enzymatic browning index (BI) model and the ANOVA results (Table 6) clearly show that the ultrasound frequency and treatment time are insignificant model terms on the non-enzymatic browning of carrot cubes during drying. The application of

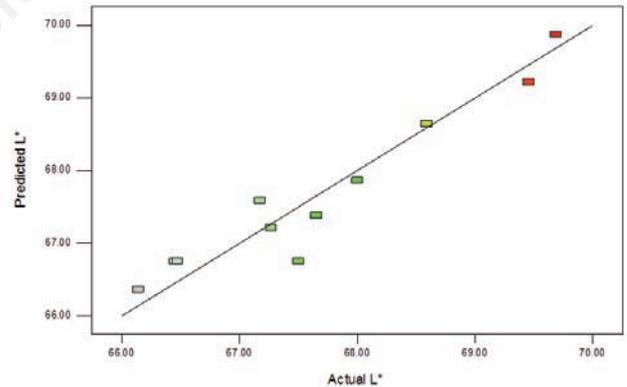

Figure 9. Predicted and simulated brightness (L^*) values.

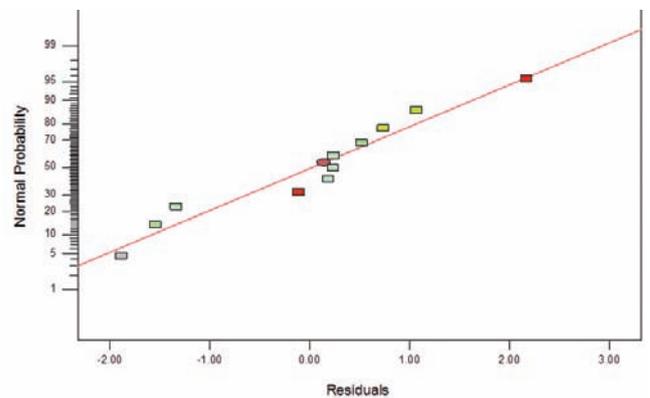

Figure 10. Normal probability plot of ratio of redness to yellowness residuals.

the ultrasound reduced the BI values in comparison with that of the control (0.414). The reduction in BI values in the ultrasonic pre-treated dried samples shows that the rate of brown pigment formation reduced with ultrasound application. Cerniřev (2010) dried tomato quarters at 50°C to 90°C and observed that the rate of browning increased with temperature from 0.585 to 0.684. Browning index equal to 0.6 was considered critical based on comparison of visual assessment of the dried

tomato samples and browning indexes of brown extracts. Browning during drying at lower temperatures (<60°C) has been found to develop proportionally to temperature and follow a zero order reaction, whereas at higher temperatures (>70°C) it showed a sharp rise.

Non-enzymatic browning is attributed to the occurrence of nitrogenous constituents and reducing sugars, nitrogenous constituents and organic acids, and sugars and organic acids in the carrot (Zanoni *et al.*,

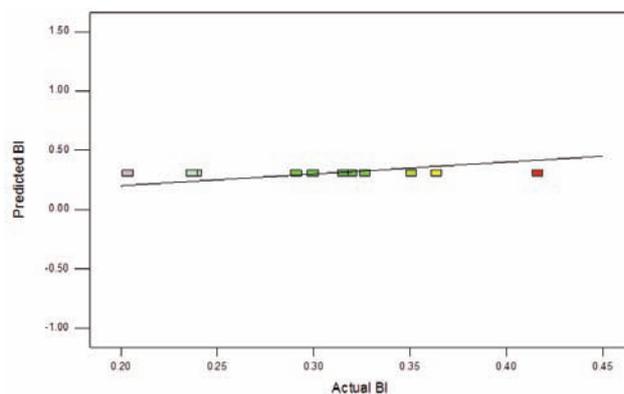

Figure 14. Predicted and simulated browning index (BI) values.

1999; Muratore, 2008; Cernișev, 2010). In this study, ultrasonic pre-treatment resulted in sugar loss and this may have reduced the BI in these samples. The effect of ultrasound frequency and sonication time on the formation of brown pigments of dried carrot by the response surface plots is shown in Figure 12. The plots of the normal probability of the residuals together with the predicted and actual non-enzymatic browning indexes are shown in Figures 13 and 14. The statistical result in Table 6 shows that the overall mean is a better predictor of BI than the quadratic model.

Conclusions

It was shown that the use of ultrasonic pre-treatment affected the water loss and sugar gain of carrot during pre-treatment and the water diffusivity of carrot during the air-drying process. The application of ultrasound caused the removal of soluble solids from the carrots, which led to the production of carrots with low sugar content. The water diffusivity increased by 30.47%, 41.79%, and 44.92% after subjecting the carrots to 32 kHz ultrasound for 10, 35 and 60 min, respectively. The flavour response signals for samples submitted to ultrasound were higher than the samples without ultrasonic pre-treatment. The increase in ultrasound frequency improved the luminance of the dried products. However, sonication time did not statistically improve the brightness of the dried carrot. The use of the ultrasound in carrot processing improved the non-enzymatic browning even though variation of ultrasound frequency and time did not significantly reduce browning.
